Abstract

Controlling disease in the soybean crop is essential for obtaining high quality seeds and high yield. This leads the producer to increase the number of fungicide applications as a preventive measure. The aim of this study was to evaluate soybean response to increase in the number of foliar applications of different chemical fungicides during crop development to enhance the physiological and sanitary quality of soybean seeds. The experiment was performed in the state of Minas Gerais, Brazil, in two environments (Ijaci and Lavras) in the 2014/15 crop year, with the cultivar BRSMG 850G®. The field experiment was conducted in randomized blocks in split-plots, with three replications. The plots were composed of the number of applications (0, 1, 2, 3, 4 and 5 times). The applications started at the R1 stage (beginning of bloom), with a 15-day interval to the next application (R1; R1+15d; R1+30d; R1+45d; R1+60d). The split-plots were constituted by the different chemical fungicides (Elatus®, Fox®, Opera®, Orkestra®, and an unregistered product - BAS – 702). Seeds were evaluated soon after harvest and after eight months of storage. The following characteristics were evaluated: seed water content, germination in paper and sand substrates, emergence, emergence speed index, mechanical damage in the sodium hypochlorite test, electrical conductivity, accelerated aging, seed vigor and viability by the tetrazolium test, and seed health, using a completely randomized design. Regardless of which fungicide was used, an increase in the number of foliar applications of fungicides, up to five applications, leads to an increase in the physiological and sanitary quality of soybean seeds, both those newly harvested and those stored for eight months. However, Fox® fungicide (trifloxystrobin + prothioconazole) applied on the leaf during the reproductive stages of the soybean crop brought about the best results in the physiological quality of newly harvested seeds and seeds stored for eight months, as well as in the sanitary quality of newly harvested seeds.

Keywords: Glycine max (L.) Merrill, phytosanitary control, seed pathology, vigor, viability.

Introduction

Due to the considerable importance of soybean in Brazilian agribusiness, studies on the factors that limit maximum expression of its yield potential are necessary. Diseases are a prominent factor, subjecting soybean to pressures that can significantly reduce yield (Quinebre, 2014) and seed quality (Carmona and Reis, 2009) through reduction in ability to produce photoassimilates, thus impairing seed formation (Bethenod et al., 2005). Approximately 40 diseases caused by fungi, bacteria, nematodes, and viruses have been identified in Brazil (Finoto et al., 2011; Vello and Carvalho, 2013). This number continues to increase due to expansion of the crop to new areas. The economic importance of each disease varies from one crop year to another and one region to another, depending on the weather conditions of each season (EMBRAPA, 2010).

Diseases in soybean can be controlled through adequate management techniques, such as the use of chemical fungicides, which have led to relevant results for the purpose of maintaining yield potential and seed quality (Marzari et al., 2007). Under wetter climate conditions, disease control through foliar fungicides can result in gain in seed quality because fungicides not only protect leaves but also preserve the integrity of pods, which, for their part, provide better protection to the seeds against adverse climate/weather conditions (Krzyzanowski et al., 2015).
The application of foliar fungicides is the most effective and immediate means of control when plants are already established in the field. Application of fungicides in a preventive manner has stood out as the most effective strategy in control of diseases (Azevedo, 2001). A longer residual period and better performance of fungicides were obtained by Vitti et al. (2004) as a result of preventive application. Thus, in recent crop seasons, the number of fungicide applications on the soybean crop has grown. In these crop seasons, four applications of fungicides were made on average, a number considered high for disease management, which foresees an average of two to three applications (Martins, 2009).

Among the inputs in the agricultural sector, high quality seed plays a fundamental role in the entire production system that aims for optimization of quantitative and qualitative standards (Silveira, 2010). When all the aspects involved in seed quality and the effects of these aspects on implementation and yield of the soybean crop are analyzed, the fundamental importance of using high quality seeds of known origin becomes clear (França Neto et al., 2010). Diverse fungicides have been registered for soybean in the Brazilian market, with different active ingredients. However, information that associates seed quality with the active ingredients available on the market for leaf application is limited. This lack of information is related to the introduction of new fungicides. Thus, with the aim of obtaining efficiency in disease control, along with high quality seeds, producers have used different products and have increased the number of fungicide applications on the crop.

In light of the above, the aim of this study was to evaluate the physiological and sanitary quality of soybean seeds, both newly harvested and after storage, in accordance with an increase in the number of foliar applications in production fields. Different fungicides for the crop were analyzed with a view toward optimizing the plant protection period.

Results and Discussion

Analysis of variance (Supplementary Table 1) indicates significant differences in physiological potential between the production locations, the number of applications, and the fungicides for the two periods of evaluation. Previous knowledge of the initial water content of the seeds is important in performing quality tests since uniformity of seed water content is indispensable for standardizing evaluations and obtaining consistent results (Marcos Filho, 1999). The results obtained were similar in the two periods of evaluation, with variation of 11% for seeds evaluated soon after harvest and 10.5% for stored seeds (Supplementary Table 1).

Effect of Production Environment

Seeds produced in the environment of Lavras had better quality than seeds in the environment of Ijaci (Table 3). This is a result of lower rainfall in the crop field in Lavras (Figure 1), especially in the reproductive stage, which had an average of 227 mm less rainfall than in Ijaci. This had a positive effect on the quality of seeds produced in the Lavras environment. Initial quality of the seed is a fundamental factor, especially in regard to soybean seed, which, by the nature of its chemical composition, already has low storage potential (Mavaieie, 2014). Preserving seed quality during storage, that is, from harvest up to the time of sowing, is a fundamental aspect to consider in the production process because efforts made in the production phase might not be effective if seed quality is not maintained up to the time of seed use (Oliveira et al., 1999).

Effect of Fungicides

The use of fungicides applied on leaves during crop development has been the focus of various studies, which show physiological effects on plants but also significant yield gains (Dourado Neto et al., 2005) and beneficial effects on seed quality (Canedo et al., 2013). When fungicides are used, they not only protect the leaves, but also preserve the integrity of the pods, which, for their part, will provide more protection to the seed against adverse weather conditions (Krzyanowski et al., 2015).

Currently in Brazil, there are diverse fungicides registered for the soybean crop, with different active ingredients. Nevertheless, information that associates seed quality with the active ingredients for foliar application available on the market is limited. Among the different fungicides used in this study, the active ingredients trifloxystrobin + prothioconazole (Fox) in general provided better quality, both for seeds evaluated soon after harvest and for stored seeds (Table 3). Analysis of physical quality through the hypochlorite test showed that application of this fungicide was related to a higher percentage of mechanical damage. However, this increase in seed damage observed did not compromise seed physiological quality.

All the fungicide treatments exhibited mean seed germination percentages higher than the minimum percentage established for sale of soybean seeds, i.e., 80% germination (Carraro and Peske, 2005). For the seeds evaluated soon after storage, the results for germination indicate that only the treatments with fungicides with the active ingredients trifloxystrobin + prothioconazole, pyraclostrobin + epoxiconazole, and pyraclostrobin + fluxapyroxad exhibited germination above the minimum levels established for sale of soybean seeds (Table 3). Similar results were observed for germination in sand, emergence, emergence speed index, electrical conductivity, accelerated aging, and vigor and viability by the tetrazolium test. Seeds in these tests exhibited decreased performance after storage, which is shown especially by reduction in the emergence speed index.

It is important to highlight that high quality seeds are important for establishing a crop. Seed performance aspects aim at increasing the germination percentage of agricultural crop species. These processes are directly related to rapid and uniform soil cover, to fast gain in dry matter, and, consequently, higher yield, significantly contributing to gains in seed production (Canedo et al., 2013).

In a study performed by Danelli et al. (2011) evaluating the quality of soybean seeds as affected by foliar treatment in the field, the authors found that the effect of the fungicides applied on the aboveground part of soybean favored seed physiological quality, and the best fungicides were those with the active ingredients pyraclostrobin + epoxiconazole and trifloxystrobin + cyproconazole. Nevertheless, Gagliardi et al. (2009), Pinto et al. (2011), and Brzezinski et al. (2012)
did not observe an effect of foliar fungicides on the physiological quality of soybean seeds.

**Effect of the Number of Applications**

In addition to the use of different active ingredients, some authors report that an increase in the number of applications of foliar fungicides during crop development has led to positive results on yield, as well as on seed quality in general. In relation to the number of applications of chemical fungicides, a similar response was found between evaluations soon after harvest and those after storage, in which an increasing number of preventive applications of fungicides, up to five applications, was essential for maintaining high quality of the seeds produced. An increase in the number of applications strengthened plant immunity to pathogens.

The results are better shown by newly harvested seeds (Figure 2), in which a linear response was found. In comparison to the control, an increase was observed in seed quality with five applications of chemical fungicides. This increase was around 5% for germination in sand, 9% for germination (Figure 2 A), 12% for the emergence speed index (Figure 2 B), 7% for seedling emergence, and 20% for accelerated aging (Figure 2 C), as well as 9% for seed vigor and 7% for seed viability, in the seeds evaluated by the tetrazolium test (Figure 2 D).

Similar results were found for seeds evaluated after eight months of storage, with increases of around 10% for germination in sand, 7% for germination (Figure 3 A), 9% for electrical conductivity (Figure 3 B), 9% for accelerated aging (Figure 3 C), and 8% for seed vigor and 9% for seed viability in the seeds evaluated by the tetrazolium test (Figure 3 D).

Similar results were obtained by Gabriel et al. (2014), who evaluated the effect of management of fungicide application on the physiological and sanitary quality of soybean seeds. The authors found a linear response with an increase in the number of applications. Carvalho et al. (2013) also found best results in the quality of soybean seeds from the maximum number of applications tested. Moreover, an increase in the number of foliar applications has reportedly been successful for enhancing the seed quality of other crops, such as rice (Telo et al., 2012).

Increasing the number of applications of fungicides resulted in higher quality of the seeds in the two periods of evaluation; however, better results were observed when seeds were evaluated soon after harvest. A higher number of applications led to an increase in germination of approximately 10% and an increase in seed vigor from 9% to 20%.

Considering that seeds are the prime input for establishing crops and that they have high added value, these results are expressive. The greater seed quality is, the more profit the seed producer will have. Gains in seed quality of any type are essential in the seed sector because production of high quality soybean seeds is a challenge for the sector, especially in tropical and subtropical regions. In these regions, production of these seeds is only possible through adoption of special techniques. When these techniques are not used, inferior quality is the result (França Neto et al., 2007).

**Phenotype correlation**

Estimates of phenotypic correlations between the number of applications and the other traits were mostly of high magnitude (Table 3). As expected, estimates were positive and high \((r \geq 0.99)\) between the number of fungicide applications and germination in paper or sand substrates, emergence, the emergence speed index, electrical conductivity, accelerated aging, and seed vigor and viability in the tetrazolium test. Knowledge of association between traits is of great importance in field research studies, especially when measuring or identifying one of the traits is difficult (Cruz et al., 2012).

**Incidence of pathogens in seeds**

From the plant health perspective, the ideal seed would be free of any undesirable microorganism. However, this is not always possible since seed quality is highly affected by the climate/weather conditions under which they are produced and stored. In addition, these conditions vary from year to year and from one region to another (Juliatti et al., 2003). In this respect, results show that the seeds produced in the municipality of Ijaci had higher proportions of pathogens, which confirms the results of physiological quality for this location (Table 3). Ijaci received higher rainfall in the crop field, especially in the reproductive stage (Figure 1), 227 mm more accumulated rainfall, on average. Comparing the evaluation periods, newly harvested seeds stand out with a higher incidence of pathogens than stored seeds. However, comparing only stored seeds, there was no difference in the proportion of pathogens between the production locations (Figure 4).

In the soybean seeds evaluated, seven pathogens were identified, namely: *Colletotrichum* sp., *Phomopsis* sp., *Fusarium* sp., *Alternaria* sp., *Cercospora kikuchii*, *Penicillium* sp., and *Aspergillus* sp. The proportion of pathogens (considering the mean of the crop locations), according to analysis of the confidence interval for proportions, shows a higher incidence of *Cercospora kikuchii* (41.89%) in newly harvested seeds and *Aspergillus* sp. (51.45%) in seeds stored for 8 months (Figures 5 A and B). There was also a higher incidence of field pathogens in newly harvested seeds (Figure 5 A); in stored seeds, there was a higher incidence of pathogens that develop better under storage conditions, as is the case of *Aspergillus* sp. and *Penicillium* sp. (Figure 5 B).

For the products used for newly harvested seeds, lower proportions of pathogens were observed when the commercial products Fox, Orkestra, and Opera were used (Figure 5 C), with a mean incidence of pathogens below 20%. The same was not observed for seeds stored for eight months, in which no difference was found among the products used (Figure 5 D).

In relation to the number of applications, the same response was observed among the newly harvested seeds and those stored for 8 months. Higher proportions of pathogens were found for the control that did not receive any fungicide application and for the treatments with only one application. From the second to the fifth application, there was a linear decrease in the incidence of pathogens (Figures 5 E and F), however, without a significant difference among the.

treatments. These results are contrary to those presented by Gabriel et al. (2014), who evaluated the effect of management of fungicide application on the physiological and sanitary quality of soybean seeds. These authors affirm that the health of soybean seeds was not affected by the number of applications of fungicide.

Materials and Methods

Description of the study environments

The experiment was conducted in the 2014/15 crop season in two different environments in the state of Minas Gerais, Brazil: on a farm in the municipality of Lavras at 21°14’S, 45°00’W, altitude of 918 m, in a soil classified as a Latossolo Vermelho Distroférico típico; and on a farm in the municipality of Ijaci, at 21°09’S, 44°55’W, altitude of 843 m, in a soil classified as a Latossolo Vermelho-Amarelo distrófico típico. The chemical attributes of the 0 – 20 cm soil layer for the two environments are shown in Table 1.

Climate in the region is Cwa according to the Köppen classification, with mean annual temperature of 19.3°C and normal annual rainfall of 1530 mm (Dantas et al., 2007). The daily climate data from the beginning of fungicide applications (Figure 1) were made available by the National Meteorological Institute (Instituto Nacional de Meteorologia – INMET).

Experimental design and trial management

In the seed production field, the experiments were conducted in a randomized block design in split-plots, with three replications. Plots were constituted by the number of applications (Table 2), and the split-plots were constituted by different chemical fungicides: Elatus® (azoxystrobin + benzovindiflupyr), Fox® (trifloxystrobin + prothioconazole),
Operá® (pyraclostrobin + epoxiconazole), Orkestra® (pyraclostrobin + fluxapyroxad), and the unregistered product BAS – 702 (pyraclostrobin + epoxiconazole + fluxapyroxad). The experimental plots consisted of 4 plant rows of 5-meter length spaced at 0.50 m, and the area of each plot was 10 m² (5 m x 2 m). The two center rows were considered the useful area, disregarding the 0.5 m at the ends of each plot.

The experiments were performed in an area under a no-tillage system over corn straw, with previous desiccation of the area using 960 g.ha⁻¹ of the active ingredient glyphosate. Sowing was performed in the first half of November in the two production environments. The cultivar BRSMG 850GAR was used, which has a determined growth habit and belongs to the relative maturity group 8.2, with a semi-late cycle (126 to 145 days) in the state of Minas Gerais. Fertilization followed the recommendations of Souza and Lobato (2004), with application of 350 kg/ha⁻¹ of the N-P₂O₅-K₂O (02-30-20) formulation in the planting furrow. Inoculation was made in the furrow after sowing, according to the methodology recommended by Embrapa (2013), with Bradyrhizobium japonicum bacteria at the rate of 18 mL of product kg⁻¹ of seed – SEMIA 5079 and 5080 strains, containing 10.8 x 10⁶ CFU/seed of the inoculant Nitragin Cell Tech HC® (3 x 10⁹ CFU/mL).

Pest and weed control was carried out according to the technical recommendations for the soybean crop (EMBRAPA, 2013). Fungicides were applied using a backpack sprayer pressured by CO₂, equipped with a two-meter boom with four Teejet XR 11002 spray nozzles spaced at 50 cm and calibrated for a flow rate of 200 liters ha⁻¹. At the time of application, the adjuvant recommended by the manufacturer was added at the rate recommended for each fungicide.

The experiments were harvested manually and threshed mechanically using the plot thresher MAQTRON® Vencedora model B – 350 STD. The seed samples in each plot were homogenized and classified by sieving. For analyses and determinations, seeds retained in 6.5 and 7 mm mesh circular sieves were used. Part of the seeds were separated for initial analysis of quality, and the rest were placed in multi-layered paper packaging and stored for eight months in an environment with constant temperature of 25ºC.

**Evaluations carried out**

For determination of quality before and after storage, seeds were subjected to the following evaluations: **Water content:** performed according to Brasil (2009), using the standard laboratory oven method at 105°C ± 3°C for 24 h, with the results expressed in percentage. **Germination:** performed according to Brasil (2009), evaluated in paper and sand substrate. **Seedling emergence:** seeds were sown in plastic trays containing soil + sand substrate at a 2:1 proportion, moistened to 60% of water retention ability – the trays were kept in a growth chamber at 25°C and 12 hour photoperiod, with daily evaluations in regard to emergence of normal seedlings and final count at 14 days after sowing. The final percentage of emergence and the emergence speed index, ESl, were considered (Maguire, 1962). **Electrical conductivity:** was carried out according to Kryzanowski et al. (1999), with assistance of a conductivity meter (MS TECNOPON® – mCA150), and results were expressed in μS.cm⁻¹.g⁻¹. **Accelerated aging:** with the use of adapted Gerbox plastic boxes with a suspended aluminum screen – 40 mL of water and a single layer of seeds were added over the screen in each Gerbox, which were then kept in a BOD chamber at 41°C for 48 hours (Marcos Filho, 1999). After this period, the seeds were subjected to the germination test (Brasil, 2009). **Tetrazolium test:** seeds were placed between moistened paper for 16 h at 25°C and then immersed in tetrazolium solution (2,3,5-triphenyl-2H-tetrazolium chloride) at 0.075%, in which the seeds remained for 3 h at 40°C, in the dark. The result was expressed by the percentage of vigor and viability (verified at levels 1 to 8), according to França Neto et al. (1998). **Mechanical damage:** through the sodium hypochlorite test according to the criteria described by Krzyzanowski et al. (2004). The samples were placed in a container and immersed in a sodium hypochlorite solution (5.25%) for 10 minutes. After that, the seeds were placed on sheets of paper towel, and the number of seeds that exhibited a seed coat that was ruptured and loose were analyzed. The results were expressed in percentage of seeds with mechanical damage. **Seed health:** for analysis of seed health, the blotted test method was used, with five replications of 40 seeds that were placed in Petri dishes over three sheets of paper, according to Limonard (1966), moistened with water + 2.4D (2,4-Dichlorophenoxyacetic acid) at 0.02%, and kept in an incubation chamber at a temperature of 20 ± 2°C and 12-hour photoperiod for seven days. Evaluations were made of individual seeds with the assistance of a stereomicroscope and optical microscope to detect the presence of pathogens associated with seeds.

**Statistical Analysis**

Combined analysis of variance was carried out, adopting the statistical model and the analytical procedure similar to those presented by Ramalho et al. (2012). Qualitative factors were clustered by the Scott-Knott (1974) test. Regression analysis was applied to study the sources of quantitative variation. Seed health was analyzed through the confidence interval for proportions, as performed by Zambiazzi et al. (2017) by the Poisson approximation at the level of 5% significance. Analyses were carried out assisted by the SISVAR® statistical package (Ferreira, 2014). Phenotypic correlation between the number of applications and the traits related to seed physiological quality was also estimated (Cruz et al., 2012) assisted by the SAS 9.0 statistical program from Statistical Analysis Systems (2008).

**Conclusion**

The fungicide Fox® (trifloxystrobin + prothioconazole) applied on leaves during the reproductive stages of the soybean crop provided the best results for physiological quality of newly harvested seeds and those stored for eight months, as well as for the sanitary quality of newly harvested seeds. An increase in the number of applications of foliar fungicides, up to five applications, leads to an increase in the physiological and sanitary quality of soybean seeds, both those newly harvested and those stored for eight months.
